GAMBLING WITH OUR PUBLIC LANDS The Scientific Uncertainty and Fiscal Waste of BLM's Vegetation Removal Program in the West

Every year, the Bureau of Land Management (BLM) spends tens of millions of taxpayer dollars

destroying hundreds of thousands of acres of native pinyon pine and juniper forests and sagebrush stands throughout the West.

These vegetation removal projects – typically done in the name of habitat and watershed "restoration" – are devastating public lands. Yet there is little evidence to support the BLM's assertion that these projects improve forage or habitat for wildlife, or reduce stream erosion and runoff.

A chained sagebrush landscape near the Paria River in Grand Staircase-Escalante National Monument, Utah.

In fact, scientific evidence often counters the claims made by proponents of vegetation treatments on public lands.

A 2019 report released by Wild Utah Project

a Utah-based non-profit organization
focused on conservation science – analyzed
the existing scientific literature on mechanical
vegetation removal projects in western
pinyon-juniper and sagebrush communities to
determine the state of current science and
identify gaps in understanding regarding
these potentially harmful projects.

Masticated pinyon-juniper landscape, Grand Staircase-Escalante National Monument in the background.

The scientific analysis raises important questions as to why the BLM is gambling taxpayer money to destroy native landscapes on our public lands.

What is a Vegetation Removal Project?

Vegetation removal projects take many forms. At the most basic level, the BLM uses:

- Chainsaws to topple pinyon pine and juniper trees before scattering sawed-up pieces around the site.
- Herbicides to kill sagebrush and pinyon and juniper saplings.
- Prescribed fire to remove tree saplings and shrubs.

The Dixie Harrow method.

Two bulldozers pull an anchor chain through pinyon-juniper forest, Utah.

A bull hog, or rotating masticator, mulches a pinyon tree.

More commonly, the BLM resorts to intensive mechanical methods, employing heavy machinery to accomplish similar ends:

- Bull Hog Masticators mow down trees with giant mulchers attached to front-end loaders or excavators. These machines turn living trees into piles of wood chips and stumps, quickly removing whole stands of native pinyon pine and juniper.
- The Dixie Harrow Method uses a tractor to drag a 25- to 50-foot-wide frame with large teeth welded to parallel bars, churning soil and uprooting vegetation.
- Chaining uses a large anchor chain, which can weigh more than 20,000 pounds, dragged between two enormous bulldozers to tear trees out of the ground, roots and all, flattening hundreds of trees with every pass. As the chains rake across the surface, soils, sagebrush, grasses, and forbs are destroyed. The discarded trees left in their wake can litter the landscape for decades.

BAD ODDS, BAD RETURNS

A Slippery Slope for Wildlife

While improvement of wildlife habitat is often a primary rationale for vegetation removal in both pinyon-juniper and sagebrush communities, existing science shows that the results of these projects are uncertain at best.

Half of the existing data points regarding the effect of vegetation removal on wildlife in sagebrush habitat show either a negative impact or "no significant effect." For projects in pinyon-juniper woodlands, the report states that "the general trend across studies was for non-significant results of mechanical removal."

PLAYING GOD: WILDLIFE WINNERS AND LOSERS

Proponents argue that mechanical treatments benefit wildlife. Science indicates that there are winners and losers when agencies conduct vegetation removal. with bird species suffering the most. Overall, mechanical treatments produce far more negative or non-significant results than positive results for wildlife.

One exception to the "non-significant results" trend was a negative impact to bird species that require pinyon-juniper habitat, such as the pinyon jay. The report notes that managing wildlife habitat is extremely complex and that "what benefits one species may be a detriment to another. . . . This argues against large expanses being treated with one method that creates a single homogenized vegetation community."

Ignoring the Effects of Livestock

According to the report, livestock grazing on public lands is "a widespread land use inextricably woven into vegetation dynamics throughout the West." The report found that the majority of research into vegetation removal "does not control for [livestock grazing], either before or after treatment."

While livestock are typically removed from the site during treatment and for 1-2 years afterwards, "few studies return and assess treatments on a longer-term basis when livestock have returned to the site."

How can a land manager ever determine the proper vegetation removal method or the success or failure of a project if livestock grazing isn't considered or analyzed? As the report states, "[f]ailing to account for the effects of livestock grazing makes it difficult to assess the causal factors of ecosystem condition and draw implications for management."

No Fix for Fire

Vegetation removal projects are often proposed for the purpose of preventing large-scale wildland fires in pinyonjuniper woodlands, but the science doesn't support this argument. According to the report, existing vegetative conditions are not always the driving cause of wildland fire and, in some instances, mechanized vegetation removal may result in increased invasive species that lead to increased fire danger.

"[R]ecent studies suggest that climate has a greater influence on fire activity than fine fuels and biomass. Other researchers found that the surface disturbances associated with mechanical treatments may facilitate cheatgrass expansion and lead to increased fires. At present, there is little research supporting the contention that removing pinyon and juniper reduces fire."

Better Ways to Restore Watershed Health

Watershed restoration is often touted as a secondary benefit to vegetation removal. While the report notes that myriad individual factors of a particular project area influence a project's benefit or detriment to ground water recharge (e.g., elevation; vegetation type; and timing, amount, and type of precipitation), existing scientific reviews "have concluded that treatments do not reliably increase water yield on a watershed scale, although water availability may increase in local areas."

Mechanical treatments disturb soils, which often leads to an increase in erosion, especially in places that rely on biological soil crusts as a component of soil stability.

Of the studies reviewed in the report, only 4% to 7% showed treatments decrease runoff and erosion. The report concludes that hand thinning of vegetation is the least disruptive method of treatment to soils.

A GAMBLE IN NEED OF REFORM

Scientific Recommendations and Conclusions

The Wild Utah Project report makes the following findings and recommendations:

- The use of passive restoration techniques, such as closing areas to livestock grazing and aerial or hand seeding of native species, "has not received enough attention in the [scientific] literature."
- **Passive restoration techniques** the cheapest, most cost-effective, and least disturbing to the target ecosystem - are often rarely considered by land managers in project proposals.
- Large-scale mechanical vegetation projects risk spreading fire-prone invasive species, which "may be a primary threat to persistence of ecosystems. The alarming possibility that treatments may facilitate continued expansion of these populations and degrade native communities calls for further scrutiny."
- Vegetation removal projects are not "one size fits all." "Planners must beware of applying the same mechanical treatments over vast areas of pinyon-juniper woodlands or sagebrush steppe vegetation communities with variable site characteristics. A careful treatment plan must be designed before implementation."
- Landscape-level projects without extensive prior study and research, as are typically proposed by land managers throughout the West, are not scientifically sound. "Practitioners should conduct small-scale, pilot field tests with the proposed treatment method before applying it on a larger scale."

- "Pilot studies should be followed by independent posttreatment scientific validation, ideally with long-term monitoring of the site, to ensure that the proposed treatment method actually does lead to the intended ecological conditions."
- Land managers need to define what constitutes "success" for a mechanical vegetation removal project. "As changing climatic conditions make predicting the results and risks of mechanical treatments even more uncertain, public land managers should aim for more transparency in the decision process to explain the expectations for a project and the science guiding the planning effort."
- While many factors may be at play in causing the majority of these projects to result in "no significant effect," "if these non-significant responses truly indicate that mechanical treatments are not producing the desired results, then a re-evaluation of their efficacy or perhaps post-treatment management is necessary."

"The removal of big sagebrush by any means in Sage Grouse winter or breeding habitats usually will have a negative or neutral effect on sage-grouse," (Beck et al. 2012; Gates 1983; Martin 1990; Robertson 1991)

Policy Recommendations

The Wild Utah Project report illustrates the need for policy reform of the BLM's vegetation removal program. SUWA suggests the BLM adopt the following guidelines for vegetation removal projects:

- Implement the least intensive, lowest risk actions first, leaving all surface-disturbing activities as a last resort. Low risk/low cost actions include removing cattle from the subject landscape and aerially seeding with native species.
- Align vegetation removal goals with the soil type of the area. For example, the BLM often argues that pinyon-juniper is "encroaching" into sagebrush habitat, but if the soil type shows that it is expected to be a pinyon-juniper forest, then the project lacks a scientific basis. Similarly, if the project area contains old-growth pinyon-juniper forest, the "encroachment" theory lacks merit.
- Take a precautionary approach to project size. Large-scale vegetation removal should not occur until the BLM develops defensible procedures and methods that ensure a high-likelihood of project success.
- Develop scientifically-robust monitoring protocols and utilize untreated reference areas to ensure that there is a baseline against which results can be compared.
- Include adequate funding for long-term monitoring and development of peer-reviewed scientific literature as part of project proposals. The BLM should partner with the U.S. Geological Survey when possible to assist in long-term monitoring.
- Analyze the impact of vegetation projects on biological soil crust and non-game species dependent on pinyon-juniper forests and sagebrush stands.
- Stop vegetation removal on wilderness-quality lands, including Wilderness Study Areas (WSAs) and BLM-identified lands with wilderness characteristics (LWCs).

For more information, visit SUWA.org/Chaining

There are millions of acres of BLM-managed public lands in the West that lack wilderness quality, where the BLM can develop and test methods and strategies for consistently achieving desired results.

Focus on prior vegetation removal project areas that have failed or underperformed before conducting surface-disturbing activity on previously undisturbed landscapes. Define meaningful goals and parameters for vegetation removal projects that define success or failure. Failing to identify specific desired outcomes limits the agency's and the public's ability to meaningfully analyze project efficacy.

The BLM should take a careful, scientifically-sound approach to vegetation removal and monitoring, rather than continuing to allow a desire for funding to determine project location and size.

EXAGGERATED BENEFITS TO WATERSHEDS

One of the primary arguments made by proponents of vegetation treatments is that the practice reduces erosion and wasteful runoff in streams. Science indicates the claimed benefits to watersheds are highly exaggerated.
